The Next Frontier: Head and Neck Cancer Immunoprevention
J. Silvio Gutkind¹ and Jack D. Bui²

Abstract

Restoring T cell–mediated antitumor immunity by targeting immune checkpoint inhibitors in head and neck squamous cell carcinoma (HNSCC) results in immunomodulation and durable remissions. However, the overall response rate to these immunotherapies in HNSCC is only approximately 20%. This raises the possibility that immunologic intervention earlier in the HNSCC continuum, such as in oral premalignant lesions (OPL) could elicit an increased therapeutic response. New experimental studies suggest that immune therapies can be used for HNSCC prevention rather than therapy. Given the current excitement for precision medicine, these findings support the future development of multimodality approaches for preventive immune oncology.

Oral Premalignancy and Chemoprevention

Every year, more than 600,000 cases of head and neck squamous cell carcinomas (HNSCC) are diagnosed worldwide. Pre-invasive tissue histologic abnormalities, such as dysplasia, often represent early to intermediate stages of the carcinogenic process during HNSCC progression. At a macroscopic level, these pre-invasive changes present as oral premalignant lesions (OPL), leukoplakia or erythroplakia (white or red patches, respectively) that have variable rates of progression to HNSCC. Unfortunately, there are still no effective therapeutic options to halt the progression of OPLs into HNSCC. To address this clinical need, our laboratory has developed a series of chemically induced oral carcinogenesis models by optimizing the delivery of a tobacco-mimetic, 4NQO, in the drinking water of C57Bl6 mice (1). This model recapitulates HNSCC progression, including the presence of easily recognizable OPLs. Using this model system, we have recently shown that the administration of metformin, the most widely used antidiabetic drug, reduces >90% the conversion of OPLs into HNSCC (1). This led to a currently open clinical trial evaluating the chemopreventive efficacy of metformin in patients with OPLs (NCT02581137).

HNSCC and Immunotherapies

Recent breakthrough discoveries have highlighted the importance of the tumor microenvironment and its associated immune cells in cancer development and therapeutic resistance. For example, HNSCCs deploy multiple mechanisms to avoid immune recognition and an antitumor immune response, including the recruitment of myeloid-derived suppressor cells and conditioning of the surrounding microenvironment to become highly immunosuppressive by expressing cytokines, such as IL6, IL10, and TGFβ, leading to the accumulation of suppressive regulatory T cells and the polarization of macrophages toward an immunosuppressive (M2) tumor-associated macrophage phenotype (2). A key emerging mechanism of tumor immunosuppression involves T-cell exhaustion, whereby T-cell reactivity is impaired due to activation of T-cell checkpoints, including PD-1, by its ligand, PD-L1 that is expressed by macrophages and some HNSCC cells restraining T-cell activation. Together, these conditions contribute to the suppression of cytotoxic CD8⁺ T lymphocyte recruitment, survival, and function, and ultimately to the loss of an effective antitumor immune response. Indeed, recent revolutionary therapeutic strategies restoring T cell–mediated antitumor immunity in HNSCC by targeting immune checkpoint inhibitors, such as PD-L1 and PD-1, demonstrated immunomodulation and durable remissions (3, 4). This led to the recent approval by the FDA of anti-PD-1 antibodies, nivolumab and pembrolizumab, for HNSCC treatment. However, the overall response rate to these immunotherapies in HNSCC is only approximately 20% (3, 4). Moreover, whether PD-L1/PD-1 acts at the OPL stage to inhibit antitumor immunity is not known.

HNSCC Immunoprevention

Unfortunately, we cannot yet predict which HNSCC patients will respond best to these immune oncology agents, and we still do not know whether immunologic intervention earlier in the HNSCC continuum, such as the premalignant state or early HNSCC lesions, could elicit an increased therapeutic response. In this regard, a study in this issue of Cancer Prevention Research has begun to address the impact of treating mice harboring 4NQO-induced OPLs with anti–PD-1 inhibitors (5). Caulin and colleagues provide exciting evidence that PD-1 blockade significantly diminishes the progression of low-grade oral SCC lesions into high-grade lesions. In this case, the authors have used heterozygous Tp53⁻/⁻ mice to accelerate OPL development in response to 4NQO. Although this approach may have skewed the mutational...
During the progression of the normal oral epithelium to head and neck squamous cell carcinoma (HNSCC), preinvasive tissue histologic abnormalities, such as low- and high-grade dysplasia, often represent early to intermediate stages of the carcinogenic process. At a macroscopic level, these preinvasive changes present as OPLs. New findings suggest that immunologic intervention with immune checkpoint inhibitors in OPL can prevent the progression of low-grade dysplasia to high-grade dysplasia, and likely to HNSCC. Given the current excitement for precision medicine, these findings support the future development of multimodality approaches as part of new preventive immune oncology strategies to halt HNSCC progression. These include the use of immune checkpoint inhibitors, cancer vaccines, and adjuvants that activate the innate immune system, such as TLR or STING agonists, alone and in combination, as well as combined with promising chemopreventive agents that have a beneficial impact in the tumor immune environment, such as metformin and COX inhibitors.

Figure 1.
During the progression of the normal oral epithelium to head and neck squamous cell carcinoma (HNSCC), preinvasive tissue histologic abnormalities, such as low- and high-grade dysplasia, often represent early to intermediate stages of the carcinogenic process. At a macroscopic level, these preinvasive changes present as OPLs. New findings suggest that immunologic intervention with immune checkpoint inhibitors in OPL can prevent the progression of low-grade dysplasia to high-grade dysplasia, and likely to HNSCC. Given the current excitement for precision medicine, these findings support the future development of multimodality approaches as part of new preventive immune oncology strategies to halt HNSCC progression. These include the use of immune checkpoint inhibitors, cancer vaccines, and adjuvants that activate the innate immune system, such as TLR or STING agonists, alone and in combination, as well as combined with promising chemopreventive agents that have a beneficial impact in the tumor immune environment, such as metformin and COX inhibitors.

Emerging Opportunities for Multimodality Precision Immunoprevention

The authors' data also suggest that the fight against cancer could begin prior to transformation (Fig. 1) and could involve a broad swath of patients. In this regard, the current excitement for neoantigen discovery, whether for use in therapeutic vaccination or in the generation of neopeptide specific T-cell therapy, represents a "holy grail" in precision immunology. It remains to be seen whether OPLs possess enough mutations to warrant a "preventive personalized vaccine." Even if OPLs have antigens, it is not clear that they are heavily infiltrated with immune cells. In this context, it is possible that the use of adjuvants that activate the innate immune system, such as TLR or STING agonists, could initiate immune responses in OPLs. For example, TLR7/8 ligands promote the recruitment and activation of innate immune cells and local antigen-presenting cells, leading to local accumulation of IFNy and induction of long-lasting adaptive immune responses against tumors (6). STING agonists can induce the production of type I IFNs and initiate self-sustaining immune responses (7). When considering the use of innate immune agonists in premalignancy, it will be important to consider the potential paradoxical tumor-promoting effects of innate cell activation. In fact, the activation of innate immune responses without antigen-specific immunogenicity during carcinogenesis may promote an inflammatory milieu that hastens cancer progression (8). In this context, one may speculate that combining anti–PD-1 with TLR agonists at a premalignant stage may actually provide an optimal antitumor response. The increased accumulation of IFNy downstream of TLR activation would increase PD-L1 expression in the microenvironment, and thus, adding anti–PD-1 would overcome this suppressive effect.

Another exciting possibility is to combine anti–PD-1 therapy with metformin or cyclooxygenase (COX) inhibitors. Besides its impact on OPL cells, metformin suppresses the polarization of protumorigenic M2-like tumor-associated macrophages and protects CD8⁺ tumor-infiltrating lymphocytes from functional exhaustion in the tumor microenvironment (9, 10). Classical COX inhibitors, including aspirin, have been recently shown to override the tumor-suppressive effect of the inflammatory mediator, PGE2, thereby synergizing with anti–PD-1 blockade in inducing the eradication of tumors (11). This raises the exciting
possibility of using metformin and/or COX inhibitors to boost the activity of immune checkpoint inhibitors, and to enhance the efficacy of anticancer prophylactic vaccines.

In summary, the authors’ findings could be interpreted to represent the innovative use of immune therapy for prevention rather than therapy. In addition, given the current excitement for precision medicine, these findings provide a much-needed spark of enthusiasm for the development of multimodality approaches for preventive immune oncology.
